Abstract

The salvage of mangled lower-extremities after severe injury remains a daunting operative dilemma, but one that continues to evolve with advances in microsurgical and orthopedic techniques. Specifically, trends in clinical practice including the decision to salvage and timing of soft-tissue coverage are changing in concordance with improvements in wound care, flap selection for soft-tissue provision, and preoperative imaging. Due to these improvements, more complex wounds are increasingly eligible for reconstruction. It remains unclear, however, whether success in limb salvage confers improved functional patient outcomes. We present a review of the literature tracing recent advances in the salvage of mangled extremities following traumatic injury, with a focus on practice trends regarding timing of reconstruction, operative approaches, and preoperative imaging.

Keywords: Lower extremity, reconstruction, propeller flaps, amputation, microsurgery, trauma

INTRODUCTION

Complex high-energy trauma to the lower extremity often entails significant and devastating morbidity for patients. Lower extremity injury accounts for greater than 250,000 hospital admissions each year in the US; more than half involve open long-bone fractures, crush, or major soft-tissue injury[1]. Return of function can be an arduous process requiring multidisciplinary care and ongoing therapy for months to years. Plastic surgeons involved in the care of these patients should be well versed in the unique demands required
by reconstruction of these complex anatomic and functional deficits. Clinical decision-making should be
guided by our developing understanding of tissue physiology, orthopedic reconstructive principles, and
developing technology used to guide preoperative planning and intraoperative decision making. When
effective, limb reconstruction can confer a close approximation of pre-morbid functionality. However,
the calculus of when, how, and on whom to intervene remains incompletely defined and often plagued
by equivocation. Fortunately, the tools used to assess the severity and distribution of injury, including
expanding use of novel imaging techniques, as well as refinement of reconstructive approaches continue
to develop. This review focuses on the advances made regarding approaches in surgical management and
perioperative assessment of complex lower-extremity injuries. Advances in orthopedic fixation, as well
as advances in the provision of soft-tissue reconstruction, guided by long-standing principles of surgical
management continue to drive the functional, aesthetic, and patient-centered outcomes conferred by limb-
salvage.

INITIAL ASSESSMENT AND DECISION TO PROCEED WITH LIMB SALVAGE

The inclination to salvage a mangled extremity, by any means necessary, is an understandable reflex
for patients and physicians alike. This inclination, however, belies the utility of amputation in restoring
functionality of patients. Data from the landmark, Lower Extremity Assessment Project (LEAP) group,
published in 2002, provide the most thorough analysis to date of lower extremity trauma treatment and
outcomes, including demographic data of the civilian population who suffer these injuries as well as
their ultimate functional status and variables surrounding their recovery[2]. The study found comparable
functional outcomes among individuals who had undergone reconstruction versus those who had
undergone amputation. Roughly one half of all patients followed for the duration of the study exhibited
significant disability as objectively assessed by the Sickness Impact Profile score. The sobering conclusion
gleaned from this multi-center study was that reconstruction conferred no functional benefit when
compared with amputation, and outcomes from both groups were poor; little more than 30% of patients
exhibited return to functionality compared with uninjured age-matched counterparts, and fewer than 60%
of patients had returned to work at seven years post-injury. These conclusions, however, should be weighed
critically, as subsequent analyses highlight the impact of socioeconomic factors, as opposed to treatment
course, as predictors of ultimate outcomes[3,4]. It should be emphasized that the LEAP trial focused on
civilian patients. Much of the literature regarding advances in lower extremity reconstruction following
high-energy trauma has been gleaned from the arena of combat. As such, treatment guidelines taken from
one patient population, while informing of the other, cannot be translated without qualification, given
distinct mechanisms of injury, concurrent trauma/injury, treatment setting, etc.[5]. Despite the multitude of
wound assessment and grading scales (discussed in more detail below), there remain no hard and fast rules
regarding when a severely damaged limb should be amputated [Figure 1]. Despite previous orthodoxy,
damage to posterior tibial nerve, and an insensate foot are no longer absolute contra-indications for limb
salvage[6,7]. Instead, reconstruction should be evaluated and approached on a case by case basis and must be
in line with the ultimate goals of the patient.

ASSESSMENT OF INJURY AND PROGNOSIS OF RECONSTRUCTION

Multiple validated grading scales exist for the purposes of assessing extremities following traumatic injury
and attempt to guide treatment accordingly. Unfortunately, all have demonstrated limited utility when
applied in the clinical setting, and there remains no gold standard of a translatable universally applicable
injury assessment tool. Nevertheless, the injury assessment scales, including the Mangled Extremity
Severity Score[7], Predictive Salvage Index[8], Limb Salvage Index[9], and the Nerve Injury, Ischemia, Soft
Tissue Injury, Skeletal Injury, Shock, and Age of the Patient[10] score, provide an objective and structured
assessment of complex injuries. Each purportedly identifies unique variables predictive of ultimate
amputation, including level of arterial injury, timing from injury to index operation, volume of soft tissue
lost, etc., which are ostensibly essential in the characterization of the injury. However, using a dataset of over 500 patients with lower extremity trauma, Bosse et al. prospectively analyzed seven commonly used injury severity scales and found these scales to have limited utility in predicting amputation versus salvage. Each of these scales demonstrated adequate sensitivity, but limited specificity, in which low scores were concordant with salvage potential, but increasing values provided no indication regarding the likelihood of amputation in injuries thought to be more severe. This work serves to cement the salience of individualized assessment and care tailored to the unique circumstances of the patient.

The Gustilo-Anderson classification of open fractures remains a relevant and commonly used assessment tool, to grade open fractures in the setting of lower extremity injury. The classification system, and subsequent modification subdivide severity of injury into three categories, each with ascending level with increasing involvement of soft-tissue, and ultimate vascular injury. This classification system, however, was devised to assess risk of subsequent infection and does not aim to predict likelihood of amputation. Nonetheless, the Gustilo classification is an effective scale with demonstrated intra-observer reproducibility.

The determinants of a patient’s prognosis following reconstruction are multiple, varied, and not solely dependent on the wound itself, timing of reconstructions, or approach to treatment; as observed in the LEAP trial, most independent risk factors for poor functional outcomes and amputation include socioeconomic circumstance of the patient’s and not the treatment plan initially employed. Again, the decision to proceed with reconstruction versus amputation is dependent on the gestalt of the patient and injury. Patients must not only overcome modifiable risk factors, and pathophysiologic sequelae of systemic disease; public perception and stigma regarding amputation continue to complicate the personal decision of whether to proceed with amputation, as well as the support network of the patient during their recovery.
TIMING OF RECONSTRUCTION

Historically, surgeons have advocated for prompt soft-tissue coverage of lower-extremity defects following trauma\(^{[16,17]}\). In his landmark study in 1986, Godina demonstrated improved rates of flap loss, infection, and length of hospital stay with soft-tissue coverage provided within the first 72-h of injury\(^{[16]}\). Three days remains the benchmark goal for acute reconstruction. Indeed, despite a trend towards a more permissive timeline of soft-tissue coverage, recent analyses corroborate improved free-flap failure rates and reduced rates of infection with immediate reconstruction within the 72-h window, although these statistical analyses remain dependent on Godina’s index cohort of over 500 patients, to date the most prolific of studies analyzed\(^{[18]}\). Obviously, surgeons strive for prompt bony stabilization and soft-tissue coverage as soon as logistically possible; however, clinical reality and the presence of concomitant injury to vital organ systems often preclude definitive reconstruction in the acute setting. Facilitated by advances in wound care, this critical window has since been liberalized in the setting of recent studies demonstrating noninferior outcomes with reconstruction in the subacute and chronic phases of injury following serial debridement without compromise of flap survival rates or patient function\(^{[17,19-25]}\). This trend has accelerated over the previous decade: the mean timing of definitive reconstruction has progressed from 6 to 12.5 days in the decade from 2002 to 2011\(^{[26]}\). This trend also reflects the prioritization of adequate wound debridement to ensure adequate preparation of the recipient wound bed. As demonstrated by Karanas et al.\(^{[20]}\), definitive soft-tissue coverage should allow for serial debridement to minimize the risk of catastrophic deep-space, or bony infection, even if this process delays reconstruction outside of the acute window. Data from the armed combat literature also underline the importance of ensuring a clean and adequately debrided wound bed\(^{[27]}\). Pollak et al.\(^{[27]}\) found that time to initial operative debridement was not an independent risk factor for the risk of infection following high-energy low-extremity trauma; however, prompt admission to definitive trauma treatment center was protective, suggesting prompt global patient management and wound care is essential to favorable reconstructive outcomes.

Perhaps more than any other therapeutic advancement, the widespread use of negative pressure wound therapy (NPWT) has proven essential for the temporization of definitive reconstruction\(^{[22,24,28]}\). Multiple hypotheses exist as to why the physiologic advantages of NPWT have facilitated the optimization of wound care including providing ideal wound healing environment via minimization of edema, reducing surface area of the wound, and providing reduced capillary afterload translating to increased perfusion of nascent granulation tissue\(^{[29,30]}\). Indeed, the physiological benefits attributed to NPWT are felt to oppose the effects of tissue fibrosis, inflammation, and edema thought to potentially threaten microvascular anastomoses driving the emphasis of early reconstruction. The use of NPWT has extended the critical time to definitive soft-tissue coverage to as far out as weeks to months from the initial injury, with numerous studies documenting comparable rates of flap loss, infection, and hospital stay following soft tissue coverage. In fact, certain cohorts report improved outcomes approaching significance of chronically reconstructed wounds compared with more acute reconstruction, lending further credence to temporization of reconstruction outside of the acute window\(^{[24]}\). As initially observed by Steiert et al.\(^{[22]}\), increasingly permissive time to definitive coverage appears concordant with the increasing complexity of the wounds being reconstructed, which helps to better understand the deviation from the 72-h orthodoxy. To be clear, when feasible, recent data still corroborate improved outcomes with earlier reconstruction. The work of Liu et al.\(^{[23]}\) demonstrated that, while delay to definitive reconstruction past seven days conferred increased risk for osteomyelitis and potential flap complications, NPWT was protective against reoperation and venous thrombosis in those populations unable to undergo acute reconstruction. Taken together, prompt reconstruction should remain the operative goal, but timing should involve nuanced considerations of the patient and injury, as excellent outcomes remain feasible long after the previously espoused 72-h window\(^{[34]}\). Unfortunately, operative considerations are not the only determinants of timing to reconstruction; the work of Shammas et al.\(^{[32]}\) identified a number of sociodemographic risk factors, including older age, nonwhite race, and geographic region for delays to soft tissue coverage. Acute reconstruction should not
be performed at the expense of patient and wound optimization, as definitive soft-tissue coverage in the subacute, and chronic intervals have been demonstrated to be safe and effective.

Soft tissue coverage is similarly dependent on the integrity of bony fixation to provide adequate tension across joints for preservation of locomotion, and to prevent collapse of soft-tissues. Fortunately, the science and practice of orthopedic reduction and fixation has developed in parallel with microsurgical techniques. Amongst the most challenging operative dilemmas from orthopedic injury is the management of resulting segmental defects. Multiple surgical strategies exist and remain used in clinical practice to restore bony length and adequate union following traumatic bone loss or defects resulting from debridement. Techniques including distraction osteogenesis (Ilizarov Technique), autologous bone grafting, and mesh implants have demonstrated adequate results regarding ultimate restoration of bone length and stability[33-35]. More recently, the Masquelet technique has emerged as a novel and reliable strategy for the purposes of restoration of bone defects[36]. Initially described in results published in 2000, the strategy utilizes staged operations to induce a periosteum surrogate, "Inflammatory Membrane", around a cement spacer, which is subsequently replaced with autologous bone graft[37,38]. Amongst multiple retrospective studies, clinical success rates have been reported in up to 89%-93% of cases, despite bony defects greater than 10 cm[39,40]. Despite the paucity of long-term functional outcomes, the technique has gained clinical traction, and has been used increasingly in concert with advances in provision of soft-tissue coverage for the purposes of lower extremity reconstruction.

**OPERATIVE CONSIDERATIONS OF RECONSTRUCTION**

Once the degree of injury has been appropriately assessed, the decision to proceed with reconstruction has been made, and the stability of the wound bed has been assured, considerations regarding the appropriate tissue to be transplanted must be made. General principles regarding the distribution of injury and corresponding donor site of soft-tissue coverage remain applicable and continue to guide surgical management. The tenets of the reconstructive ladder remain applicable when reconstructing lower extremity injuries. Often, despite significant fractures, local muscle flap coverage and skin grafting provide excellent results. However, given unique challenges posed at certain areas, namely around the knee and proximal tibia, as well as the distal leg, ankle, and foot, surgeons are increasingly utilizing more complex solutions, as espoused by the "reconstructive elevator" paradigm. As conceived and popularized by Gottlieb and Krieger[41], the reconstructive elevator argues for skipping over simpler solutions in favor of a reconstructive approach that more accurately approximates the functional and anatomic deficits of the injury. For instance, given the paucity of tissue, and resulting exposure of bony and articulating surfaces, free-flap reconstruction has become the default surgical option for injuries of the distal lower extremity.

While certain micro-surgical principles have remained unchallenged, recent data have led to the liberalization of other reconstructive dogmas held by many practicing surgeons. The requirement of a clean wound bed for recipient tissue remains an immutable tenet of reconstruction. The translation of autologous tissue should only occur in a clean wound-bed free of necrotic or infected tissue, and preferably over appropriately reduced bony framework. In contrast, discussion regarding the selection of autologous tissue to be harvested as well as the selection of recipient vasculature continues to evolve. Recently, a trend towards the use of perforator fasciocutaneous flaps has proportionately displaced the use of bulkier myofasciocutaneous free-flaps[42]. Improved understanding of perfasomes, and increasing facility with perforator dissection have resulted in the wide-spread adoption of using fasciocutaneous flaps for extremity reconstruction[42,43]. Despite concerns that the use of fasciocutaneous flaps preclude the superior blood supply conferred by transferred muscle, these flaps are no more prone to ischemia and flap failure. Similarly, fasciocutaneous flaps are resistant to shear and breakdown in weight bearing areas when compared with muscle containing flaps[44]. That being said, multiple “work-horse” flaps provide appropriate
tissue qualities for corresponding defects: the latissimus dorsi flap provides significant tissue bulk for large tissue deficits, the neurotized gracilis flap provides potential for restoration of active motion, etc. In a span of 30 years, microsurgical flaps have become common practice in lower extremity reconstruction. There remains a disproportionately high rate of complications of free-flaps in microsurgical reconstruction, with a 14% rate of major complications cited in a retrospective review of over 400 injuries. Independent risk factors for flap compromise include prolonged operative time, preoperative anemia, steroid use, and diabetes.

Other considerations, including selection of recipient vessels, remain of paramount importance. Clinical orthodoxy favors selection of vessels proximal to the site of injury, given progressive decrease in size of available source vessels more distal in the leg. However, this orthodoxy has recently been challenged by select institutions, as selection of recipient vessels distal to the site of injury was recently demonstrated to be non-inferior in a retrospective review of 312 free-tissue transfers for soft-tissue reconstructions of open tibial fractures. This remains a point of contention, but feasibility provides an alternative in the event of complication precluding more proximal access.

A common paradigm in the reconstruction of lower extremity remains the anatomic subdivision of the leg into thirds: proximal, middle, and distal. The distal third provides unique reconstructive challenges due to paucity of local tissue available for local tissue rearrangement, and superficial distribution of structures requiring coverage. As such, the distal third of the leg manifests the opportunity to put the principles of the “reconstructive elevator”, into practice, yet remains plagued by higher rates of complications. Free-flaps remain the preferred option for reconstruction of substantial deficits in this region. However, comparison of free-flap coverage demonstrates increase rates of free-flap loss, and complications at the distal third of lower extremity injuries, when compared to more proximal leg injuries. The use of propeller flaps has arisen as a viable option for soft-tissue coverage when free-tissue transfer is contraindicated, or simply not feasible. Propeller flaps provide substantial soft-tissue for coverage of essential structures via improved understanding of perfosome distribution without need for microanastomosis in precarious anatomic regions. Historically, perforator flaps had been thought to require thick cuffs of subcutaneous tissue to protect the pedicle from kinking, thereby restricting the arc of rotation, and often resulted in dog-ears at the axis of rotation. As understanding of perfasomes has advanced, including the course and distribution of these short branching vessels, local pedicled flaps have been used with increasing regularity for lower extremity reconstruction. Particularly in the distal third of the lower extremity, multiple local flaps including the reverse sural fasciocutaneous flaps can be used with regularity to reconstruct complex defects, and can be staged as delayed flaps without any question of tissue viability. More proximally, muscle flaps, such as the anterior tibial and soleus flaps, can be translated to cover bony defects following trauma, further establishing the role of local pedicled flaps in soft-tissue reconstruction of the lower extremity.

ADVANCES REGARDING IMAGING TECHNOLOGY TO ASSESS LOWER EXTREMITY INJURY

Imaging in the setting of complex injury can be used to not only evaluate the viability of limb salvage, but also to orient eventual reconstruction via the identification, localization, and qualitative assessment of potential recipient vessels for purposes of microvascular reconstruction. Hard signs of ischemia, including hemorrhage, expanding hematoma, and absent distal pulses, are sufficient to prompt operative intervention to ensure continued perfusion of the distal extremity; in the absence of obvious signs, however, modalities used for assessment of vascular injury remain variable and institution dependent.

The “gold standard” of evaluating vascular injury remains arteriography, but this modality is limited by persistent rates of iatrogenic injury, commonly cited at 1%-5%, as well as increased timing of
performance and cost to the hospital system\cite{53,54}. Since its introduction in clinical practice in the early 1990s, computed tomographic angiography (CTA) has become the de-facto diagnostic modality of choice to assess vascular injury in the setting of lower-extremity trauma\cite{55}. Due to a more favorable side-effect profile, as well as imaging resolution comparable to that of angiography, CTA has begun to replace arteriography as the preferred diagnostic modality to evaluate vascular injury\cite{56,57}. Despite the obvious advantage of predisposing patient’s to less ionizing radiation and the avoidance of complications such as pseudoaneurysm, vessel thrombosis, and vessel injury, the routine use of CTA has long been continuously debated but has gained routine acceptance in clinical practice\cite{58}. While CT imaging may demonstrate vascular injury, and patency of residual vessels, this modality does little to evaluate flow in potential donor vessels to sustain microvascular reconstruction in the setting of collateral flow. Furthermore, the sensitivity of CTA is limited in the identification of vasospasm and local injury\cite{59}. For these reasons, many institutions continue to rely on arteriography for preoperative imaging and planning. In individuals whose renal function preclude administration of iodinated dyes, carbon dioxide angiography remains a viable and underutilized imaging modality\cite{60,61}. Compared with iodinated contrast, CO$_2$ angiography decreases the incidence of acute kidney injury from 11.1% to 4.7%. As such, CO$_2$ angiography may provide valuable diagnostic data in populations unable to receive large contrast loads secondary to compromised renal function or adverse reactions to iodinated contrast.

When microvascular reconstruction is required, recipient vessel selection outside the zone of injury is of paramount importance, made more so by the limitations conferred by the associated injury. Some institutions argue for the continued utility of obtaining formal arteriography, but primarily in the setting of chronic lower extremity wounds, as these studies may demonstrate previously unrecognized vascular pathology and allow for prompt endovascular intervention facilitating ultimate reconstruction\cite{62}. Others argue that any diagnostic imaging in the setting of trauma is superfluous, as thorough clinical examination and intraoperative adaptation are sufficient to conduct soft-tissue reconstruction\cite{63}.

Figure 2. A: adult male following degloving injury to left lower extremity; B: preoperative marking for posterior tibial artery perforator propeller flap; C: immediate postoperative result, medial view; D: immediate postoperative result, lateral view.
However, preoperative vessel imaging remains common practice in the traumatic setting. Similar to the evolution of imaging for the purposes of injury identification, vessel selection has evolved from the transition from angiography to CTA over the previous decade. For the purposes of free-flap planning, Duymaz et al. were able to demonstrate the utility of obtaining lower extremity CTAs in correlating arterial injury with eventual flap loss, although no direct comparisons were made to preoperative angiography. As previously mentioned, routine use of CTA provides excellent assessment of lower-extremity anatomy without the associated co-morbidities of formal angiography. Development of ancillary imaging modalities to assess perforator vessel for preoperative planning continues to evolve. Recent work by Feng et al. suggests the use of color doppler ultrasound demonstrates greater fidelity of identifying and localizing dominant perforators of lower extremity flap when compared to CTA in a head-to-head comparison. The use of Indocyanine green (ICG) has also emerged as an adjunctive imaging modality to assess the microvasculature of perforator and local tissue flaps in microsurgical reconstruction. ICG is a cyanine dye with near-infrared spectral absorbance that binds circulating plasma proteins. As such, ICG in concert with near infrared imaging has been used across multiple medical disciplines for the purposes of vascular and lymph perfusion imaging. In the field of plastic surgery, ICG has been used with increasing frequency for the purposes of local, perforator, and free-flap perfusion distribution. Most published studies to date use ICG to assess viability of skin flaps of the trunk, head, and neck. The technology was recently demonstrated, albeit in a limited series of 23 patients, to significantly improve complication rates of tissue necrosis and deep-space infection in patients with Gustilo Type IIIB when used as an adjunct to guide initial debridement. While its use has yet to be routinely adopted, ICG has proven a reliable adjunct available to clinicians to assess tissue perfusion in the operating room.

**CONCLUSION**

Advances in microsurgical techniques, the advent of negative pressure wound technology in temporizing wound care, and improvements in preoperative imaging have facilitated changing treatment practices in the reconstruction of traumatic lower extremity injuries over the previous two decades. Despite persistent challenges, as evidenced by high rates of postoperative infection, flap loss, and poor functional recovery,
reconstruction has become increasingly available for injuries previously thought to be unsalvageable. The pre-existing dogma advocating for immediate soft-tissue reconstruction within a 72-h window has since been liberalized in the setting of improved wound-care, the widespread use of negative pressure wound therapy, and the advent of damage-control orthopedic surgery, allowing reconstruction of increasingly complex injuries in severely sick patients. The improved understanding of perfosomes and refinement of microsurgical technique have facilitated the paradigm of the reconstructive elevator to more closely approximate pre-morbid anatomy and function. The use of ancillary imaging including CTA, angiography, and doppler ultrasound has refined the identification and characterization of recipient vessels for free-tissue transfers. As technological advances continue to augment preoperative assessment, routine wound care, and intraoperative planning, reconstruction will continue to more closely approximate pre-injury functionality, improving patient outcomes and satisfaction.
