Abstract

Although near-infrared phosphor-converted light-emitting diodes (NIR pc-LEDs) are desired for non-visible light source applications, the design of broadband NIR phosphors remains a challenge. Inspired by the chemical unit co-substitution strategy for the modification of composition and local structure, we realize a tunable redshift emission from 706 to 765 nm in garnet-type Lu$_3$Sc$_2$Ga$_3$O$_{12}$:Cr$^{3+}$ with a broadened full width at half maximum and enhanced photoluminescence intensity by introducing a [Mg$^{2+}$-Si$^{4+}$] unit into the [Sc$^{3+}$-Ga$^{3+}$] couple. Structural and spectral analyzes demonstrate that the co-substitution reduces the local symmetry and crystal field strength of the [CrO$_6$] octahedra, thus leading to inhomogeneous widening of the $^4T_2 ightarrow ^4A_{2g}$ emission and enhanced blue absorption. Furthermore, the $^4T_2 ightarrow ^4A_{2g}$ emission exhibits a phonon-assisted character at low temperatures due to the thermal coupling effect with the $^2E$ level. The fabricated NIR pc-LED based on the optimized NIR phosphor exhibits excellent potential in night vision and imaging applications.

Keywords: Near-infrared (NIR), garnet structure, Cr$^{3+}$-doped phosphor, co-substitution
INTRODUCTION

Broadband near-infrared (NIR, 700–2500 nm) light sources are urgently needed for a variety of applications, including component detection\(^1\), phototherapy\(^1\), agricultural plant lighting\(^2,3\), bioimaging\(^4\), night vision illumination\(^5\) and iris recognition\(^6\). Among various NIR light sources, however, traditional halogen tungsten lamps suffered from high-power dissipation\(^7\). Electroluminescent semiconductors, such as GaAs, are inappropriate for various applications due to their narrow emission band\(^8,9\). Furthermore, organic light-emitting diodes (LEDs) suffer from low hydrothermal stability\(^10\). In contrast, NIR phosphor-converted (pc)-LEDs that are encapsulated by blue light InGaN chips and NIR-emitting phosphors are emerging as promising candidates to achieve the desired broadband NIR emission. Owing to the commercialization of high-efficiency blue chips\(^11,12\), the development of NIR phosphors pumped by blue light with broadband and tunable emission has become a research priority\(^13\).

So far, several types of NIR phosphors have been explored by doping Eu\(^{2+}\)\(^{13,15}\), B\(^{3+}\)\(^{16}\), Ni\(^{2+}\)\(^{17}\), Mn\(^{3+}\)\(^{18}\) and Cr\(^3+\) into inorganic hosts. Among these dopants, Cr\(^3+\) has gradually become the focus of attention for practical applications due to its high photoluminescence quantum yield\(^19–21\), broadband and tunable emission\(^22,23\) and high thermal stability\(^24–26\). In addition, the \(A_{1g} \rightarrow T_{1g}\) transition of Cr\(^3+\) perfectly matches the blue light chip, as well as a narrowband or tunable broadband emission sensitive to the crystal environment due to the 3\(d^3\) electronic configuration. Among the different hosts for Cr\(^3+\) doping, garnet-type compounds possess a compact structure with high symmetry belonging to the cubic system\(^27\) and have been extensively studied for high-performance NIR phosphors.

The garnet-type structure is composed of three kinds of polyhedra, namely, dodecahedra, mainly occupied by elements with large radii, such as rare earth elements and alkali and alkaline earth metals, octahedra, occupied by transition and main group metals with small radii, and tetrahedra, usually occupied by Ga, Si, Ge, Al, V and P. In recent years, Cr\(^3+\)-doped garnet phosphors with high internal quantum efficiency (IQE) have been reported and studied. However, owing to the parity-forbidden character of \(d\cdot d\) transitions, Cr\(^3+\)-doped phosphors suffer from a low absorption coefficient (Abs) and narrow emission band. This is particularly true for highly symmetrical lattices, including Ca\(_5\)Sc\(_2\)Si\(_3\)O\(_{12}\)\(_{:}\)Cr\(^{3+}\) (IQE/Abs = 92.3%/27.6%, FWHM = 110 nm)\(^29\) and Gd\(_5\)Sc\(_3\)Ga\(_2\)O\(_{12}\)\(_{:}\)Cr\(^{3+}\) (IQE/Abs = 98.6%/21.0%, FWHM = 120 nm)\(^29\), which limits the further application of NIR pc-LEDs. Although the Abs can be raised by increasing the concentration of Cr\(^3+\), excessive dopants usually lead to serious concentration quenching effects and stronger electron-phonon coupling, resulting in damage to the thermal stability and IQE in the garnet structure\(^30,31\). Although Cr\(^3+\) and Yb\(^{3+}\) co-doping may benefit the broadening emission spectrum and enhance the thermal stability, it has little effect on improving the Abs\(^32\). It has been reported that introducing the odd-parity crystal field by lattice distortion can partly release the parity-forbidden character of Cr\(^3+\) ions so that an improved Abs is expected\(^31\).

In recent years, the chemical unit co-substitution strategy, i.e., the simultaneous substitution of two kinds of chemical units in a crystal structure, has been used to realize structural evolution and the regulation of luminescence properties, as proposed by our group and successfully adopted by many different research teams\(^34\). Benefitting from the high structural tolerance of the garnet structure, chemical units can enter the cell in large quantities to realize the distortion of the polyhedra and the disorder of the local crystal environment, further breaking the reverse symmetry of the crystal site, where Cr\(^3+\) is located. Thus it leads to a strong crystal field splitting and contributes to the photoluminescence tuning of the emission band.

In this work, an enhanced NIR emission of Cr\(^3+\) ions with a broadened FWHM is realized by co-substituting [Mg\(^{2+}\)-Si\(^{4+}\)] for [Sc\(^{3+}\)-Ga\(^{3+}\)] in garnet-type Lu\(_3\)Sc\(_{1-x}\)Mg\(_x\)Ga\(_{2-x}\)Si\(_3\)O\(_{12}\)\(_{:}\)0.02Cr\(^{3+}\) phosphors. The luminescence...
properties and crystal field strength of the phosphors are further studied as a function of x. We find that the thermal coupling effect of the $^4T_2$ and $^2E$ levels and the electron-phonon coupling effect are enhanced with increasing x and the related luminescence mechanism is proposed. Finally, a broadband NIR pc-LED is designed and fabricated using the composition-optimized phosphor Lu$_3$Sc$_{1.38}$Mg$_{0.6}$Ga$_{2.4}$Si$_{0.6}$O$_{12}$:0.02Cr$^{3+}$ (LSMGS:Cr) and its applications in imaging and night vision illuminating are demonstrated.

MATERIALS AND METHODS

Materials and preparation
The Lu$_3$Sc$_{1-x}$Mg$_x$Ga$_{3-x}$Si$_x$O$_{12}$:0.02Cr$^{3+}$ samples ($x = 0.0, 0.30, 0.45, 0.60, 0.75$ or $0.90$) were prepared by a conventional high-temperature solid-state method. Lu$_2$O$_3$ (99.9%, Aladdin), Sc$_2$O$_3$ (99.9%, Aladdin), MgO (99.9%, Aladdin), Ga$_2$O$_3$ (99.99%, Aladdin), SiO$_2$ (99.99%, Macklin) and Cr$_2$O$_3$ (99.95%, Aladdin) were used as the starting materials and weighed according to stoichiometric proportions, with $2\text{ wt.}\%$ H$_3$BO$_3$ (99.5%, Aladdin) added as the flux. After being mixed and grounded thoroughly using ethanol in an agate mortar, the mixtures were transferred into alumina crucibles (Kaiping Shengxing Chemical Porcelain Factory, Tangshan, 16 x 28 mm) and then placed in a box furnace for sintering at 1450 °C for 6 h in air. Finally, the phosphors were ground in an agate mortar for 3 min after cooling to room temperature.

Characterization
Powder X-ray diffraction patterns were measured using a diffractometer (PANalytical Corporation, Netherlands) with a Cu Ka radiation source ($\lambda = 1.5406$ Å) and the operating voltage and current set as 40 kV and 15 mA, respectively. Room-temperature photoluminescence (PL) and photoluminescence excitation (PLE) spectra were recorded using an FLS1000 fluorescence spectrophotometer (Edinburgh Instruments, UK) equipped with a continuous xenon lamp (450 W) as the excitation source and a liquid-nitrogen cooled NIR photomultiplier tube as the detector (Hamamatsu, R5509, InP/InGaAsP). Low-temperature spectra were measured using the same spectrophotometer equipped with a Cryo-77 low-temperature fluorescence instrument (Tian Jin Orient - KOJI Instrument Co., Ltd.). The PL decay curve was also measured using the same spectrophotometer with a microsecond flash lamp ($\mu$F900) as the excitation source. High-temperature spectra were measured by a fiber spectrophotometer (NOVA high-sensitivity spectrometer, Idea Optics, China) equipped with a TAP-02 high-temperature fluorescence instrument (Tian Jin Orient - KOJI Instrument Co., Ltd.) and a 450 nm laser diode as the excitation source. Diffuse reflection (DR) spectra were collected using a UV-Vis-NIR spectrophotometer (Hitachi UH4150) and BaSO$_4$ was used as the reference standard. The quantum efficiency at room temperature was measured by an absolute PL quantum yield spectrometer (Quantaurus-QY Plus C13534-12, Hamamatsu Photonics).

LED device fabrication and performance measurements
The pc-NIR LED device was designed and made by coating the as-prepared phosphor on a blue LED (X1901, 5 W, Guangzhou LEDteen Optoelectronics Co., Ltd., China) and fully blending with an epoxy resin. The electroluminescence of the fabricated NIR pc-LED was measured by Optical & Electrical Fast Meters For LEDS (Hangzhou Hopoo Optoelectronics Technology Co., Ltd., China).

RESULTS AND DISCUSSION
Crystal structure of Lu$_3$(Sc, Mg)$_2$(Ga, Si)$_3$O$_{12}$:Cr$^{3+}$
The phase and purity of the as-prepared powder samples were examined by X-ray diffraction and the results are shown in Figure 1A. The x value reflects the degree of co-substitution of [Mg$^{2+}$-Si$^{4+}$] for [Sc$^{3+}$-Ga$^{3+}$]. All diffraction peaks were well matched with the standard data of the Lu$_3$Sc$_3$Ga$_3$O$_{12}$ cubic phase (PDF No. 54-1252, space group la-3d) and no obvious impurity phases were observed, indicating that the phase of the samples was not affected by a certain amount of chemical unit co-substitution due to the high structural tolerance of garnet-type compounds as shown in Figure 1C.
Figure 1. (A) XRD patterns of Lu$_3$Sc$_{1.98-x}$Mg$_x$Ga$_{3-x}$Si$_x$O$_{12}$:0.02Cr$^{3+}$ ($x = 0.0-0.9$) with selected diffraction peak near 32.7°. (B) Calculated lattice parameters of Lu$_3$Sc$_{1.98-x}$Mg$_x$Ga$_{3-x}$Si$_x$O$_{12}$:0.02Cr$^{3+}$ ($x = 0.0-0.9$). (C) Crystal structure of Lu$_3$Sc$_{1.98-x}$Mg$_x$Ga$_{3-x}$Si$_x$O$_{12}$:0.02Cr$^{3+}$.

The shift of the strongest diffraction peak to a higher angle, as shown in Figure 1A, indicates that the cell shrinks with increasing $x$. With the substitution of [Mg$^{2+}$-Si$^{4+}$] for [Sc$^{3+}$-Ga$^{3+}$], the diffraction peak near 32.7° shifts slightly toward a higher angle [Figure 1A] due to the ionic radii of Mg$^{2+}$ (0.72 Å, coordination number (CN) = 6) and Si$^{4+}$ (0.26 Å, CN = 4) being smaller than that of Sc$^{3+}$ (0.745 Å, CN = 6) and Ga$^{3+}$ (0.47 Å, CN = 4), respectively [35]. The lattice parameter of the phosphors in the cubic system was calculated using the Bragg equation:

$$2d \sin \theta = \lambda$$

(1)

$$\frac{1}{d^2} = \frac{h^2 + k^2 + l^2}{a^2}$$

(2)

where $d$ and $a$ represent the interplanar spacing and lattice parameter, respectively. The wavelength of the incidence X-ray $\lambda$ was 1.5406 Å. The diffraction peak position $\theta$ originating from the crystal face $(hkl)$ was obtained from the strongest diffraction peak near 32.7° in Figure 1A, where $h$, $k$ and $l$ are the Miller indices, namely, 0, 2 and 4, respectively, in the calculation. The lattice parameter decreased from 12.32 to 12.23 Å with increasing $x$, as shown in Figure 1B. This indicates that the [Mg$^{2+}$-Si$^{4+}$] chemical unit had been successfully incorporated into the garnet-type structure. The shrinkage of the crystal cell usually enhances the crystal field strength of the octahedrally-coordinated Cr$^{3+}$ center with a blueshift and narrowed emission band. In contrast, a completely opposite phenomenon in Lu$_3$Sc$_2$Ga$_{3}$O$_{12}$:Cr$^{3+}$ can be observed after the [Mg$^{2+}$-Si$^{4+}$] chemical unit was introduced, as discussed below.
Photoluminescence properties of Lu$_3$(Sc, Mg)$_2$(Ga, Si)O$_{12}$:Cr$^{3+}$

The room-temperature emission (PL) and excitation (PLE) spectra of Lu$_3$Sc$_{1.98}$Ga$_3$O$_{12}$:0.02Cr$^{3+}$ are shown in Figure 2A. Under the excitation of 440 nm blue light, Lu$_3$Sc$_{1.98}$Ga$_3$O$_{12}$:0.02Cr$^{3+}$ exhibits a dark-red emission with a FWHM of 88 nm centered at 706 nm, which is attributed to the $^2E \rightarrow ^4A_{2g}$ transition of Cr$^{3+}$. When monitored at the 706 nm emission, Lu$_3$Sc$_{1.98}$Ga$_3$O$_{12}$:0.02Cr$^{3+}$ gave three excitation bands in the UV, blue and red regions, which were assigned to the $^4A_{2g} \rightarrow ^4T_1$ ($^4P$), $^4A_{2g} \rightarrow ^4T_1$ ($^4F$) and $^4A_{2g} \rightarrow ^4T_2$ ($^4F$) transitions of Cr$^{3+}$, respectively. After the [Mg$^{2+}$-Si$^{4+}$] unit replaces the [Sc$^{3+}$-Ga$^{3+}$] couple in the structure, the emission band position gradually shifts from 706 to 765 nm. Furthermore, the FWHM is doubled to 176 nm [Figure 2B].

The Lu$_3$Sc$_{1.38}$Mg$_{0.6}$Ga$_{2.4}$Si$_{0.6}$O$_{12}$:0.02Cr$^{3+}$ phosphor has a broadband NIR emission with stronger penetrability and crypticity, which is more conducive to its application in biological imaging and component analysis compared to Lu$_3$Sc$_{1.98}$Ga$_3$O$_{12}$:0.02Cr$^{3+}$ with a narrowband visible dark-red emission.

The change in the spectrum can be divided into two stages, as shown in Figure 2C. In the first stage ($x = 0.0-0.45$), the emission band position rapidly redshifts and the FWHM increases significantly, mainly as a result of the enhancement of the broadband $^4T_2 \rightarrow ^4A_{2g}$ emission, indicating that the excited electrons gradually tend to populate at the $^4T_2$ state rather than the $^2E$ state. The enhancement of the parity-forbidden $^4T_1 \rightarrow ^4A_{2g}$ transition is a common phenomenon in garnet oxide solid solutions\cite{36} and is usually caused by the disordered local crystal environment of Cr$^{3+}$ due to the introduction of the chemical unit. In the second stage ($x = 0.6-0.9$), the values of the emission band position and FWHM increased slowly and finally converged to a constant. This may be caused by two competing factors. The first is the crystal field enhancement caused by the lattice contraction discussed previously, which usually engenders the blueshift and sharpens the Cr$^{3+}$ emission. The second factor is the disordered local crystal environment, which usually engenders the redshift and broadens the Cr$^{3+}$ emission.

Because of the lack of protection from an external shell, the orbital energy levels of the $d$ orbital of Cr$^{3+}$ are very sensitive to the influence of the host lattice. Therefore, to explore the further influence of the [Mg$^{2+}$-Si$^{4+}$] chemical unit substitution on the emission properties of Cr$^{3+}$, it is necessary to quantitatively calculate the crystal field splitting parameters, including $Dq$, $B$ and $C$. According to crystal field theory, the crystal field strength parameter $Dq$ and Racah parameter $B$ can be approximated by the following equations\cite{37}:

\begin{equation}
10Dq = E(T_{1g})
\end{equation}

\begin{equation}
\frac{Dq}{B} = \frac{15(\Delta E / Dq - 8)}{(\Delta E / Dq)^2 - 10(\Delta E / Dq)}
\end{equation}

\begin{equation}
\Delta E = E(T_{1g}) - E(T_{2g})
\end{equation}

Finally, the Racah parameter $C$ can be calculated by:

\begin{equation}
E(^2E) = 3.05C + 7.9B - 1.8B^2 / Dq
\end{equation}

where $E(T_{1g})$ and $E(T_{2g})$ are the energy levels of $^2T_{1g}$ ($^2F$) and $^2T_{2g}$ ($^2F$) for Cr$^{3+}$, respectively, which can be obtained from the PLE spectra, and $E(^2E)$ is the equilibrium position of the sharp zero-photon line (ZPL) obtained from the PL spectra.

The Racah parameter $B$ represents the repulsion between electrons in the $3d$ orbital of Cr$^{3+}$. The value of the Racah parameter $B$ of Cr$^{3+}$ in the host is usually lower than in the free environment ($B_0 = 918$ cm$^{-1}$) and
strongly depends on the covalency of the host. Accordingly, the specific crystal field parameters of Lu$_{12}$Sc$_{1.98-x}$Mg$_x$Ga$_{3-x}$Si$_3$O$_{12}$:_0.02Cr$^{3+}$ (x = 0.0, 0.6 or 0.9) were calculated, as listed in Table 1. The value of $Dq$/$B$ decreases from 2.85 to 2.65 with increasing $x$ value, thus reducing the energy separation between $^4T_{2g}$ and $^2E$ [Figure 2D]. The decreased $B$ values indicate that the ionic character of the octahedra in which Cr$^{3+}$ is located is enhanced due to the enlargement of the [Sc/MgO]$_6$ octahedra, even though the whole crystal cell shrinks under co-substitution. Therefore, the excited electrons will tend to reside in the gradually redshifted $^4T_{2g}$ level due to the weakening crystal field and induction of a broad NIR emission ($^4T_{2g} \rightarrow ^4A_2$). As shown in Figure 2E, with increasing $x$, the integral intensity of Lu$_{12}$Sc$_{1.98-x}$Mg$_x$Ga$_{3-x}$Si$_3$O$_{12}$:_0.02Cr$^{3+}$ increased to 180% of the original value at first (x = 0.0-0.6) and then decreased (x = 0.6-0.9). Figure 2F shows the DR spectra of the Lu$_{12}$Sc$_{1.98-x}$Mg$_x$Ga$_{3-x}$Si$_3$O$_{12}$:_0.02Cr$^{3+}$ series. The three absorption bands of Cr$^{3+}$ in the UV-Vis region fit well with the three excitation bands of the PLE spectra. With the introduction of [Mg$^{2+}$-Si$^{4+}$] chemical units in the structure (x = 0.0-0.6), the reflectance at 440 nm reduces from 81.9% for $x$ = 0.0 to 67.4% for $x$ = 0.6, which indicates that more blue light was absorbed by the optimized phosphor.

The external quantum efficiency (EQE) of the designed phosphors is crucial for high-performance NIR LEDs and is the product of the internal quantum efficiency (IQE) and Abs. The quantum yield of the samples was measured and the values of the EQE, IQE and Abs are shown in Figure 3A. The matrix garnet phosphor (x = 0.0) shows a high IQE of up to 81.4% and a low Abs (0.257) due to the parity-forbidden transition of Cr$^{3+}$. The [Mg$^{2+}$-Si$^{4+}$] co-substituted phosphor (x = 0.6) demonstrated a higher EQE (28.1%) compared to the matrix phosphor (20.9%) on account of the improvement of the absorption ability from 25.7% (light green body color) to 38.4% (deep green body color). Excessive [Mg$^{2+}$-Si$^{4+}$] chemical units were harmful to the luminescence ability of the Lu$_{12}$Sc$_{1.98-x}$Mg$_x$Ga$_{3-x}$Si$_3$O$_{12}$:_0.02Cr$^{3+}$ phosphors (x = 0.75 or 0.90), which is consistent with the trend of the integral intensity of the PL spectra [Figure 2E]. The decreased trend of the Abs of Lu$_{12}$Sc$_{1.98-x}$Mg$_x$Ga$_{3-x}$Si$_3$O$_{12}$:_0.02Cr$^{3+}$ phosphors (x = 0.75 or 0.90) may be caused by more...

serious diffuse reflection due to the mismatched refractive index between the garnet phase and the impurities.

The experiment results show that the PL decay curves can only be fitted with a bi-exponential function [Figure 3B]:

$$I(t) = A_1 e^{-t/\tau_1} + A_2 e^{-t/\tau_2}$$  \(7\)

where $I(t)$ represents the emission intensity at a certain time $t$, $A_1$ and $A_2$ are constants and $\tau_1$ and $\tau_2$ are the luminescence decay times. According to the above equation, the decay times were determined to be 406.1, 218.4 and 195.3 $\mu$s for $\tau_1$ and 185.1, 58.6 and 56.0 $\mu$s for $\tau_2$, corresponding to the $x = 0.0$, 0.6 or 0.9 samples, respectively. It is known that Cr$^{3+}$ generally exists stably at octahedral sites. Although Cr$^{3+}$ will occupy both octahedral and dodecahedral sites in some garnet oxides, the PL band of Cr$^{3+}$ at dodecahedral sites usually exhibits longwave PL (> 800 nm) due to the larger radius of the polyhedra. Thus, the bi-exponential PL decay was more likely caused by one crystallographic site with multiple local crystal environments.
The two lifetimes with different orders can be attributed to the $^2\text{E} \rightarrow ^4\text{A}_{2g}$ and $^4\text{T}_{2g} \rightarrow ^4\text{A}_{2g}$ transition, respectively. The $^2\text{E} \rightarrow ^4\text{A}_{2g}$ transition is both parity-forbidden and spin-forbidden, while the $^4\text{T}_{2g} \rightarrow ^4\text{A}_{2g}$ transition is parity-forbidden but spin-allowed, which causes the former to have a longer lifetime. The transition from the $^2\text{E}$ state becomes partially allowed due to the overlap between the wavefunctions of the $^2\text{E}$ and $^4\text{T}_2$ states, which explains the shorter decay time in the phosphors after co-substitution. This phenomenon suggests that the excited electrons are populated at both the $^2\text{E}$ and $^4\text{T}_2$ levels, which further indicates that Cr$^{3+}$ in Lu$_2$Sc$_{1.98-}\text{Mg}_{0.02}\text{Ga}_{0.02}\text{Si}_{1.98}\text{O}_{4}\text{SiO}_{4}$ may possess more than one set of $Dq/B$ values, which also explains why the total crystal field strength calculated in Figure 2D was not at a medium level and the inhomogeneous broadening in the PL spectra. The bi-exponential decay of the matrix may be caused by anti-site defects, which were previously reported in Lu$_2$Sc$_{1.98-}\text{Mg}_{0.02}\text{Ga}_{0.02}\text{Si}_{1.98}\text{O}_{4}\text{SiO}_{4}$. Overall, co-substitution will induce a local structural distortion and then introduce sites with weaker crystal field strength, as well as the partial lifting of the forbidden $^4\text{T}_{2g} \rightarrow ^4\text{A}_{2g}$ transition due to the high symmetry. The phenomenon where two luminescence components in the inhomogeneous broadening PL spectra can be detected when monitored at a certain wavelength, indicating the nonnegligible thermal coupling of the $^2\text{E}$ and $^4\text{T}_2$ levels, as discussed below. The PL lifetimes decreased with increasing $x$ [Supplementary Figure 1] due to the partial lifting of the restriction on the forbidden transition and the increase in the probability of the non-radiative transition.

To investigate the detailed luminescence mechanism herein, the low-temperature-dependent PL spectra and PL decay curves of LSMGS:Cr were recorded and compared in Figure 3C, Supplementary Figures 2 and 3. At 80 K, the PL spectra of LSMGS:Cr consist of a sharp ZPL, namely, the $^2\text{E} \rightarrow ^4\text{A}_{2g}$ transition at 690 nm and the attached Stokes sideband (705 and 720 nm) due to the participation of phonons. The $^4\text{T}_{2g} \rightarrow ^4\text{A}_{2g}$ transition presented as a broadband emission centered at 785 nm. With increasing temperature, the intensity of the $^2\text{E} \rightarrow ^4\text{A}_{2g}/^4\text{T}_{2g} \rightarrow ^4\text{A}_{2g}$ transition enhanced at first and then decreased significantly when the temperature exceeded 125 K. This similar phenomenon related to the ZPL and Stokes sideband also exists in other transition metal-doped phosphors with the 3$d^1$ electronic configuration, such as V$^{3+}$ and Mn$^{4+}$[42,43]. The dopants in the host introduce local defects, which can accept energy from not only photons but also phonons in the host lattice to produce luminescence. The latter, known as phonon-assisted emission, will be enhanced by more phonons according to the Bose-Einstein distribution law when heating from a low temperature. When the temperature is raised to a specific level, the large number of phonons induces serious electron-phonon coupling, which leads to thermal quenching.

The $^4\text{T}_{2g} \rightarrow ^4\text{A}_{2g}$ emission with the same behavior was abnormal compared to other Cr-doped phosphors. Generally, phosphors at low temperatures exhibit a stronger emission because the lattice vibration is inhibited, which weakens the electron-phonon coupling effect and causes a smaller probability of non-radiative transition. The abnormal $^4\text{T}_{2g} \rightarrow ^4\text{A}_{2g}$ PL behavior related to the temperature indicates that the thermal coupling effect between the $^2\text{E}$ and $^4\text{T}_2$ levels did exist in Lu$_2$Sc$_{1.98-}\text{Mg}_{0.02}\text{Ga}_{0.02}\text{Si}_{1.98}\text{O}_{4}\text{SiO}_{4}$ so that the phonon energy can transfer between these two levels by back-intersystem crossing/intersystem crossing (blsc/lsc)[44]. The phonon-assisted emission was also present in the solid solution with $x = 0.45$, as shown in Supplementary Figure 4. In addition, the PL decay also can be fitted with a bi-exponential function with a reduced lifetime compared with that at 80 K due to the increasing portion of $^4\text{T}_{2g} \rightarrow ^4\text{A}_{2g}$ emission during the blsc process and more serious electron-phonon coupling. In the Cr-doped phosphor, weakening of the crystal field strength caused by lattice thermal expansion with increasing temperature leads to a redshift in the PL spectra. In LSMGS:Cr, however, the emission center with a larger Stokes shift will suffer more serious thermal quenching, resulting in the 20 nm blueshift of the emission spectrum at high temperature, which is common in disordered local crystal environment, such as Cr-doped glasses[45], which further proves the disorder of the local structure in LSMGS:Cr. Even though the non-radiative transition to some extent exists in the LSMGS:Cr, it still retains 75% at 423 K of the initial intensity measured at room temperature.
and maintains fine color stability [Figure 3D and Supplementary Figure 5], which benefits from the high structural rigidity of the garnet.

In summary, the mechanism of \([\text{Mg}^{2+}-\text{Si}^{4+}]\) co-substitution on the regulation of optical properties can be qualitatively explained, as shown in Figure 3E and F. The \([\text{Mg}^{2+}-\text{Si}^{4+}]\) chemical units not only introduce more multiple local crystal environments but also reduce the energy level gap \(\Delta E_c\) between \(\text{4T}_{2g}\) and \(\text{2E}\), which is closely related to the crystal field strength. Thus, the energy level thermal coupling enhances, which allows part of the excited electrons at the \(\text{2E}\) level can also populate into the \(\text{4T}_{2g}\) level through the back-intersystem crossing process with increasing \(x\) and eventually leads to the transition from a short wavelength sharp emission to a long wavelength broad emission. However, the weak crystal field strength simultaneously causes the reduction of the thermal activation barrier \(\Delta E_a\), which causes more serious electron-phonon coupling and thermal quenching, thereby weakening the luminescence performance, which is consistent with the results of the luminescence analysis and thermal stability [Figures 2E and 3A; Supplementary Figure 6].

**Application in a NIR pc-LED**

To demonstrate the potential application of NIR pc-LEDs in night vision illumination and the penetrating imaging of biological tissue, a broadband NIR pc-LED device was designed and fabricated using the LSMGS:Cr (\(x = 0.6\)) phosphor on a blue light-emitting InGaN chip (440 nm), as shown in Figure 4A. The NIR output power continuously increases with the drive current and reaches 90.3 mW at 100 mA. Furthermore, the photoelectric efficiency of pc-LED drops from 8.73% to 5.74% due to the efficiency drop of LED chips, as shown in Figure 4B. Figure 4C shows that a bouquet can be vividly captured by a NIR camera.
using a 720 nm long-pass filter under the non-visible illumination of the NIR pc-LED, which shows the feasibility of its application in night vision. The veins of a human palm can be distinguished, as shown in Figure 4D, using NIR light to penetrate and a NIR camera to capture, because NIR light has a good penetrability through biological tissue and veins have a specific absorption of NIR light. This fundamental demonstration indicates that the LSMGS:Cr phosphors can be potentially applied in machine vision and non-destructive examination.

**CONCLUSIONS**

Broadband NIR phosphors Lu$_{2-x}$Sc$_{x}$Mg$_{x}$Ga$_{3-x}$Si$_{x}$O$_{12}$:0.02Cr$^{3+}$ ($x = 0.0$-$0.9$) with tunable emission were successfully fabricated by a high-temperature solid-state method. The shrinkage of the crystal cell and pure phase were verified by XRD analysis. By co-substituting [Sc$^{3+}$-Ga$^{3+}$] with [Mg$^{2+}$-Si$^{4+}$] chemical units in the garnet host with high symmetry, the [CrO$_6$] octahedra were distorted, thus breaking the inversion symmetry and leading to the broadband $^4T_2 \rightarrow ^4A_2$ emission. Furthermore, the [Mg$^{2+}$-Si$^{4+}$] pairs strengthened the thermal coupling between the $^4T_2$ and $^2E$ levels due to the weakened crystal field strength, resulting in both sharp ZPL and broad emissions. Under 440 nm blue light excitation, the composition-optimized garnet-type solid solution demonstrated an inhomogeneous widening NIR emission maximized at 765 nm, with a large FWHM of 176 nm and highest EQE/Abs of 28.2 %/38.4% for the composition of $x = 0.6$ (Lu$_{2.38}$Sc$_{1.38}$Mg$_{0.6}$Ga$_{2.4}$Si$_{0.6}$O$_{12}$:0.02Cr$^{3+}$). The fabricated broadband NIR pc-LED showed a light outpower of 90.3 mW at 100 mA with a photoelectric efficiency of 7.5%, demonstrating its application potential in multiple fields.

**DECLARATIONS**

**Authors' contributions**
Conceived and drafted the manuscript: Xia Z, Wang T
Prepared material and device, performed characterization: Wang T
Performed data analysis: Wang T, Liu G
Revised the manuscript: Xia Z

**Availability of data and materials**
The data that support the findings of this study are available from the corresponding author upon reasonable request.

**Financial support and sponsorship**
The work was supported by International Cooperation Project of National Key Research and Development Program of China (2021YFB3500400 and 2021YFE0105700), the National Natural Science Foundations of China (Grant Nos. 51972118), Guangzhou Science & Technology Project (202007020005), and the Local Innovative and Research Teams Project of Guangdong Pearl River Talents Program (2017BT01X137).
