Abstract

Aim: About a third of patients with autism spectrum disorder (ASD) receive pharmacological treatment for comorbid symptoms. However, 30%-50% do not respond adequately and/or present severe and long-lasting side effects. Previous studies have reported the influence of variants in genes coding for drug targets on the efficacy and safety of pharmacological treatments, including genetic polymorphisms in dopaminergic and serotonergic systems. However, most studies have focused on the adult population, with relatively few studies in children and adolescents, and no clear biomarkers of response have been reported in these populations. The aim of our study was to identify genetic predictors of drug response in patients with ASD. This information may be used to personalise pharmacological treatment and improve the efficacy and safety of psychotropic drugs in patients with ASD.

Methods: Genetic variants in dopaminergic and serotonergic drug targets (SLC6A3, DRD2, DRD3, DRD4, HTR2A, and HTR2C) and in other genes previously associated with treatment efficacy and/or induced side effects (ANKK1, BDNF, COMT, and HTR1A) were investigated in 176 children and adolescents diagnosed with ASD and undergoing pharmacological treatment.
**Results:** A SLC6A3 genetic variant was associated with response to methylphenidate in our ASD cohort, whereas HTR2A and HTR2C allele and haplotype distributions were associated with adverse reactions such as somnolence, mood alterations, and BMI. ANKK1, COMT, and BDNF genetic variants were mainly associated with treatment side effects.

**Conclusion:** If confirmed, these genetic variants may be used as predictors of clinical outcome and help to personalise pharmacological treatments in patients with ASD.

**Keywords:** Autism, pharmacogenetics, methylphenidate, antipsychotic, antidepressant, dopamine, serotonin

**INTRODUCTION**

Autistic spectrum disorders (ASD) are severe neurodevelopmental alterations characterised by deficits in social communications and repetitive and restricted behaviours. Although there is no specific pharmacological treatment for ASD, about a third of patients receive pharmacological treatment for comorbid symptoms. Stimulant, antipsychotic, and antidepressant drugs are used for the treatment of conduct, anxiety, and mood disorders observed in patients with ASD. Pharmacotherapy with methylphenidate is the preferred treatment for attention deficit hyperactivity disorder (ADHD) comorbid symptoms, as well as antipsychotics and selective serotonin reuptake inhibitors antidepressants for the treatment of aggression and mood disorders. However, there is significant individual variability in the response to pharmacological treatment. Not all ASD subjects respond to treatment, with 30%-50% not responding and/or presenting with severe and long-lasting side effects, including increased irritability, aggressiveness, and somnolence\(^1\). Furthermore, children and adolescents are more susceptible to drug-induced side effects than adults\(^2\). Treatment failure and side effects have a negative effect on patients with ASD, and predictors of response for the personalisation of pharmacological treatment are required.

There is strong evidence of the influence of genetic factors on the clinical outcome of pharmacological treatments. Previous studies have reported the influence of variants in genes coding for targets of psychotropic drugs on the efficacy and safety of pharmacological treatments. The dopaminergic and serotonergic systems, both major targets for psychotropic drugs, have been implicated in the modulation of treatment outcome\(^1,3,4\). Enzymes involved in the metabolism of catecholamines and proteins involved in stress and mood alterations have also been implicated in the modulation of treatment response\(^3,5,6\). However, relatively few pharmacogenetic studies have been performed on drug treated ASD subjects.

The clinical outcome of psychotropic drugs varies between children and adults\(^7\). Most studies have focused on the adult population, with relatively few studies in children and adolescents. Several studies have associated genetic variants in the gene coding for the dopamine transporter (SLC6A3), a direct target of methylphenidate in children and adolescents affected by ADHD\(^7,8\). Variants in genes coding for dopaminergic receptors type 2, 3, and 4 (DRD2, DRDRD3, and DRD4, respectively) have also been associated with response to methylphenidate in young ADHD subjects\(^6,9,10\). Findings of association between polymorphisms in genes coding for the adrenergic receptor 2A (ADRA2A), brain derived neurotrophic factor (BDNF), catechol-O-methyltransferase (COMT), serotonin receptor 2A (HTR2A), serotonin transporter (SLC6A4), norepinephrine transporter (SLC6A2), and methylphenidate clinical outcome in young ADHD subjects have been reported in independent studies\(^7,11,12\). However, these findings have not been universally replicated or showed inconsistent results\(^7\). A meta-analysis by Bonvicini et al\(^{13}\) did not support an association of a polymorphism in the 3'-untranslated region (UTR) in the dopamine transporter (SLC6A3) with response to methylphenidate. Significant associations between variants in dopamine receptors 1, 3, and 4 (DRD1, DRD3, and DRD4), ADRA2A, COMT, SLC6A3, and SLC6A4 genes and response
to methylphenidate have been detected in a sample of 64 children with ASD[14]. A study by Correia et al.[15] described the influence of genetic variants in the multidrug resistance 1 (MDR1 or ABCB1) gene on clinical improvement with risperidone therapy in \( N = 45 \) ASD patients. Furthermore, associations between treatment response and polymorphisms in \( BDNF, HTR2A, \) serotonin receptor 2C (HTR2C), serotonin receptor 6 (HTR6), and cytochrome P450 2D6 (CYP2D6) genes were reported in the same study. However, these findings were not conclusive. Considering the limited number of pharmacogenetic studies in ASD and the moderate sample sizes, further investigation is required to identify predictors of response that could improve the efficacy and safety of pharmacological treatments in this population group.

The aim of our study was to identify genetic predictors of drug response in a population group who are particularly susceptible to adverse reactions. This information may help to improve the efficacy and safety of pharmacological treatments in children and adolescents with ASD.

**METHODS**

**Study samples**

A total of \( N = 176 \) children (86% boys and 14% girls, average age = 11.77 ± 4.64 SD) diagnosed with ASD according to DSM-5 criteria and undergoing pharmacological treatment (\( N = 146 \) with methylphenidate and \( N = 30 \) with antipsychotic, antidepressant, anxiolytics, and mood stabilizers) for at least 8 weeks were included in the study. Treatment response was assessed using the Aberrant Behaviour checklist, (ABC-CV, Aman et al., 1985), Autism Treatment Evaluation Checklist (Rimland & Edelson, 1999), Clinical Global Impression-Severity (CGI-S) for autism symptoms, Conners Rating Scale-Revised for parents and teachers for the assessment of ADHD symptoms (Conners, 1997), Child Behaviour Check list for parents, and Teacher’s Report Form for teachers to assess general child psychopathology symptoms. Response to pharmacological treatment was assessed retrospectively from the parents’ CGI categorical scores (0 = poor response, 1 = some response, 2 = good response, 3 = very good response). Global side effects were assessed with a score between 0 and 3 (0 = no side effects, 1 = mild side effects lasting less than two weeks, 2 = moderate side effects lasting more than 2 weeks, 3 = bad side effects with long lasting side effects of more than a month of duration or intolerable side effects resulting in suppression of medication). Specific information on the presence or absence of aggression, shutdowns, irritability, mood alterations, and somnolence were obtained via parents’ interviews. This sample has a statistical power \( \geq 85\% \) to detect moderate effect sizes (\( f \geq 0.25, \alpha = 0.05 \)). This project was approved by the Ethics committee of the Hospital Universitari Mutua Terrassa. Informed consent was obtained from all participants or their legal carers prior to introduction in the study.

**Genetic characterisation**

Selected candidates included genes coding for dopaminergic and serotonergic drug targets (SLC6A3, DRD2, DRD3, DRD4, HTR2A, and HTR2C) and other genes previously associated with treatment efficacy and/or induced side effects (ANKK1, BDNF, COMT, and HTR1A). DNA was extracted from whole blood samples using a commercial kit (EZNA SQ Blood DNA Kit II, Omega Bio-Tech, USA) and following manufacturers’ instructions. Sixteen single nucleotide polymorphisms (SNPs) and variable number tandem repeats (VNTRs) within the 10 selected genes were genotyped using iPLEX Gold chemistry and the MassARRAY platform (CEGEN-PRB2-ISCIII, University of Santiago de Compostela, Spain) for the SNPs and agarose gel genotyping methods for the VNTRs. Table 1 contains a complete list of the genotyped polymorphisms. Polymorphisms were selected based on previously reported associations with response to pharmacological treatment.

**Statistical analyses**

Multivariate analyses, including gender, age, drug type, and dose as covariables, were conducted for each single polymorphism analysed. Haplotype analyses were also conducted within those genes with more than one polymorphism genotyped. Separate analyses were also conducted for the subgroup of patients treated with methylphenidate. Statistical analyses were performed using the statistical package PLINK (version 1.07.2).\(^{[16]}\)

**RESULTS**

All SNPs and individuals investigated showed genotyping success rates over 95%. Additionally, all genotyped SNPs were in Hardy-Weinberg equilibrium and were included in the analyses. Table 1 summarises the results of the multivariate analyses in the study sample. Single marker analyses including gender, age, drug type (i.e., methylphenidate, antipsychotics, antidepressants, or others), and dose as covariates did not reveal any significant association with the level of response to pharmacological treatment in patients with ASD. The ANKK1 rs1800497 polymorphism was associated with presence of side effects (\( P = 0.03 \)) as were SNPs in BDNF (rs6265, \( P = 0.03 \)) and COMT (rs4680, \( P = 0.02 \)). Analyses of specific side effects revealed association between the HTR2A rs6314 polymorphism and mood alterations (\( P = 0.03 \)). The level of somnolence was associated with BDNF (rs6265, \( P = 0.03 \)) and SLC6A3 (3' UTR VNTR, \( P = 0.02 \)) variants. Finally, COMT and HTR2A variants (rs4680 and rs6314, respectively) were nominally associated with BMI (\( P = 0.04 \) and \( P = 0.05 \), respectively). Haplotype analyses (data facilitated on request) revealed association between HTR2A allelic combinations and mood alterations, presence of somnolence, and BMI (\( P = 0.02 \), \( P = 0.01 \), and \( P = 0.04 \), respectively). A HTR2C haplotype was significantly associated with BMI (\( P = 0.005 \)). Finally, a DRD3 haplotype was nominally associated with the presence of shutdowns (\( P = 0.04 \)). No other statistically significant associations were observed.

Table 2 summarises the results in the subgroup of ASD subjects treated with methylphenidate. The 3' UTR VNTR variant in SLC6A3 was associated with response to methylphenidate (\( P = 0.03 \)) and the BDNF rs6265 polymorphisms was associated with the presence of side effects (\( P = 0.03 \)). No other single marker association was detected. Haplotype analyses within this subgroup revealed association between HTR2C

NA: Not available.

Allelic combinations and response to methylphenidate treatment \( (P = 0.02) \) and BMI \( (P = 0.02) \). Association was also observed between a HTR2A haplotype and mood alterations \( (P = 0.04) \). Finally, a DRD3 allelic combination was associated with presence of side effects \( (P = 0.05) \).

**DISCUSSION**

We aimed to identify genetic predictors of response to pharmacological treatment by investigating 16 SNPs and VNTRs within 10 candidate genes and their influence on clinical outcome in a cohort of \( N = 176 \) children and adolescents with ASD. Several significant associations were observed that may help to identify patients with ASD likely to show poor response and/or develop side effects.

Previous evidence indicates that variants in dopaminergic genes are associated with emotional dysregulation and ADHD symptoms in patients with ASD\[^{17}\] and with methylphenidate response in children with ADHD\[^{6,9,18-21}\], although these findings have not been universally replicated\[^{22-24}\]. We investigated polymorphisms in several dopaminergic genes including SLC6A3, DRD2 (and the ANKK1 Taq I), DRD3, and DRD4, and their possible relation to symptom improvement after pharmacological treatment in ASD children.

We did not find association between the SLC6A3 3’ UTR VNTR variant investigated and treatment response in the study sample that included subjects treated with a variety of psychotropics. Nevertheless, the SLC6A3 3’ UTR VNTR variant was associated with somnolence \( (P = 0.02) \) in the total cohort and with response in the subgroup of methylphenidate treated patients. Interestingly, previous studies have reported association between this variant and response to methylphenidate in children with ADHD\[^{14,20}\]. The dopamine transporter is a direct target of methylphenidate, a drug widely used in the ASD population for the treatment of ADHD co-morbid symptoms. Although suggestive, these results require further investigation. An association was observed between the ANKK1 rs1800497 polymorphism (alternative nomenclature: DRD2 Taq I) and presence of side effects in the study cohort \( (P = 0.03) \). Interestingly, a
previous study reported this polymorphism associated with insulin-resistance in patients with ASD treated with risperidone\[^{25}\]. We did not find any significant association with the other dopaminergic variants investigated (\textit{DRD2} rs18012028, \textit{DRD3} rs167771 & rs6280, and a 48bp repeat in \textit{DRD4}), although \textit{DRD3} haplotype combinations were found nominally associated with shutdowns in the total sample (\textit{P} = 0.04) and with side effects in the methylphenidate subgroup (\textit{P} = 0.05). Previous studies reported association between the \textit{DRD3} rs6280 polymorphism and methylphenidate response in a group of 64 children with ASD\[^{14}\] and risperidone response in a sample of 45 patients with ASD\[^{19}\]. These findings require further investigation in larger samples to confirm the possible contribution of \textit{DRD3} variants to treatment response variability in ASD.

Abnormalities in the serotonergic system have been implicated in several psychiatric disorders. A significant reduction of serotonin type 1A and 2A (\textit{5-HT1A} and \textit{5-HT2A}) receptor binding densities was observed in brain regions of patients with ASD\[^{26}\]. \textit{HTR1A} variants, including rs878567, have been associated with ADHD risk\[^{27}\]. \textit{HTR2A} polymorphisms have also been associated with depression, gastrointestinal disorders, and risk in patients with ASD\[^{28-32}\]. Several studies have associated \textit{HTR2A} and \textit{HTR2C} polymorphisms with response to antipsychotic and antidepressant drugs as well as weight gain or increased BMI during antipsychotic treatment\[^{33-34}\]. \textit{HTR1A} variants have also been shown to associate with antipsychotic response\[^{61}\] but not with antidepressant outcomes\[^{59}\]. In our study, we found significant associations between the \textit{HTR2A} rs6314 (His452Tyr) polymorphism and BMI and mood alterations. Carriers of the Tyr452 variant, with reduced functionality\[^{37}\], were more likely to experience mood alterations and somnolence during treatment but showed less BMI. Haplotype analyses of \textit{HTR2A} allele combinations showed significant findings with mood alterations (\textit{P} = 0.02), somnolence (\textit{P} = 0.01), and BMI (\textit{P} = 0.04) in the total cohort and with mood alterations in the methylphenidate subgroup (\textit{P} = 0.04). These findings seem to agree with previous studies that linked \textit{HTR2A} variants with BMI during pharmacological interventions\[^{33,38}\] and with major depression\[^{39}\].

The serotonin 2C (\textit{5-HT2C}) receptor modulates eating behaviour and has been reported to influence antipsychotic-induced weight gain and BMI\[^{3,16,40}\]. Although we did not observe single marker associations, we found significant associations between \textit{HTR2C} haplotype combinations and BMI in the study sample (\textit{P} = 0.005) and between overall response (\textit{P} = 0.02), as well as between BMI (\textit{P} = 0.01) in the subgroup of methylphenidate patients. Previous studies had also reported association between \textit{HTR2C} genetic variants and response to psychotropic treatments\[^{3}\]. Finally, we did not find any significant association between the two \textit{HTR1A} polymorphisms genotyped, rs6295 and rs878567, and the phenotypes investigated.

\textit{BDNF} is a protein that modulates stress and mood alterations and several studies link \textit{BDNF} altered levels with ASD\[^{41}\]. It has been reported that methylphenidate treatment increases \textit{BDNF} serum levels in children with ADHD\[^{20,42}\]. \textit{BDNF} genetic variants may contribute to ASD pathogenesis\[^{43}\] and methylphenidate response in children with ASD\[^{44}\]. Our own results showed an association between the \textit{BDNF} rs6265 variant and presence of side effects (\textit{P} = 0.03 for both the study cohort and the methylphenidate subgroup) during pharmacological treatment in children with ASD. Additionally, patients carrying the Met66 allele showed higher levels of somnolence (\textit{P} = 0.03 in total cohort). However, we were not able to find association between the rs6265 Vall66 allele and response to methylphenidate (\textit{P} = 0.26) as previously reported in Korean children with ADHD\[^{44}\]. Reports of association between the rs6265 polymorphism and aggression in patients with schizophrenia were not confirmed by us and other investigators\[^{45}\]. Correia et al.\[^{15}\] found association between the Met66 allele and higher prolactin levels during risperidone treatment of children in ASD, although no direct association with risperidone response was detected. Insulin resistance during risperidone treatment was associated with this polymorphism in adolescents with ASD\[^{29}\]. These results,
taken together, suggest that genetic variation in \textit{BDNF} contributes to adverse reactions rather than to the efficacy of pharmacological treatment in ASD subjects. However, the possible role of these genetic variants on BDNF plasma levels and their contribution to treatment side effects need further investigation.

\textit{COMT} is one of the main enzymes involved in the degradation of catecholamines including dopamine, epinephrine, and norepinephrine, whose pathways are targeted by methylphenidate and other psychotropics. The \textit{COMT} rs4680 (Val158Met) polymorphism has been associated with methylphenidate response in children and adolescents with ADHD\cite{19,48-50} and children with ASD\cite{14}. Furthermore, the level of irritability was predicted by \textit{COMT} variants in children with ADHD treated with methylphenidate\cite{48}. The \textit{COMT} rs4680 variant was not associated with treatment response in our sample, but was marginally associated with presence of side effects, with rs4680-G/G (Val/Val) individuals presenting more lasting side effects ($P = 0.02$) and BMI ($P = 0.04$) in the study cohort.

In summary, we observed several associations between the candidate genes analysed and clinical outcome in patients with ASD treated with a variety of psychotropics. A \textit{SLC6A3} genetic variant predicted response to methylphenidate in our ASD cohort, whereas \textit{HTR2A} and \textit{HTR2C} allele and haplotype distributions were mainly associated with adverse reactions such as somnolence, mood alterations, and BMI. \textit{ANKK1}, \textit{COMT}, and \textit{BDNF} genetic variants were mainly associated with treatment side effects. These associations resembled those observed in other pathologies, suggesting a similar mechanism of action in ASD and/or confirming the common origin of the symptoms treated.

Our study has several limitations. None of the findings reported in this study survived multiple analyses corrections, considering the number of polymorphisms and phenotypes analysed. Our findings require confirmation in independent studies. The study sample size is moderate, which may have affected the statistical significance of the findings and produced false positives or negatives. However, it is one of the largest cohorts collated for ASD pharmacogenetic studies. Furthermore, most of our findings coincide with the pharmacogenetic results observed in other pathologies, suggesting they are true findings. Another limitation is that we did not investigate functional variants in drug metabolising hepatic enzymes. Although there is extensive evidence on the influence on functional variants in cytochrome P450 (CYP) metabolic enzymes on treatment response, the main drug used in our study cohort, methylphenidate, is metabolised mainly by CES1. Inconsistent results on the genetic influence of CES1 variants on treatment response have been reported\cite{51,52}. However, reports of associations between genetic variants in CYP enzymes and response to psychotropic treatment in children with schizophrenia or ASD merit further investigation in independent studies\cite{2,53}.

In conclusion, our study showed that genetic variation in dopamine (\textit{SLCA3}) and serotonin (\textit{HTR2A} and \textit{HTR2C}) may influence response to psychotropic treatment in patients with ASD and side effects, whereas \textit{ANKK1}, \textit{COMT}, and \textit{BDNF} polymorphisms may contribute to adverse reactions. Associations between the \textit{SLC6A3} and methylphenidate response have been reported in other pathologies and may constitute a useful biomarker for the selection of adequate treatment. The genetic associations with adverse reactions may help to predict or prevent the development of side effects, although their value to discriminate between treatments is unclear. Nevertheless, if confirmed these genetic variants may be used as predictors of clinical outcome and help to personalise pharmacological treatments in patients with ASD.

\textbf{DECLARATIONS}
\textbf{Authors’ contributions}
Study design, sample recruitment, data analyses, results interpretation, and paper writing: Hervas A
Genotyping, data analyses, and results interpretation: Serra-Llovich A, Cárcel M, Amasi-Hartoonian N, Hernandez M
Sample recruitment and results interpretation: Rueda I, Targa I, Guijarro S, Bigorra A, Cancino M, Bote V
Study design, data analyses, results interpretation, and paper writing: Arranz MJ

Availability of data and materials
Clinical and genotyping data were collected by our team and can be provided on request.

Financial support and sponsorship
Fondos Investigación Sanitaria, Instituto de Salud Carlos III, PI11/0260.

Conflicts of interest
Dr. Amaia Hervas has consulted for Exeltis and given seminars sponsored by Shire. Dr. Hervas participates in several clinical trials. None of these activities have influenced the present study. No other interests were declared by the rest of the co-authors.

Ethical approval and consent to participate
This study complies with the Declaration of Helsinki and has been approved by our Hospital Ethics Committee, as mentioned in the methods section.

Consent for publication
Not applicable.
